Abstract

A cross sectional study was carried out from October to December 2011 with the objectives of determining the prevalence of ovine lungworms and assessing the associated potential risk factors in Merhabete district, North Shoa Administrative Zone, Amhara National Regional State. A total of 384 faecal samples were collected from randomly selected sheep for the examination of first stage larvae using modified Beermann technique. Of these 52.34% were found positive for lungworm infection. The lungworm parasites identified were include *D. filarial*, *M. capillaries* and mixed infection with prevalence of 35.42%, 7.55% and 9.37%, respectively. Among the potential risk factors assessed in the present study clinical signs, body condition and agro-climate were found to have significant association and play important role in the occurrence of lungworm infection. The prevalence was higher in animals showing clinical signs (67.77%), having poor body condition (63.89%), and originated from midland (57.95) than others. However, there was no statistically significant ($p > 0.05$) between the occurrence of ovine lungworm and the factors sex and age groups. In conclusion, this study indicated that lungworms are important internal parasites in the study area which impairs the productivity of sheep, implying the need for control intervention.

Keywords: Faecal; Lungworms; Merhabete district; Ovine; Prevalence

Introduction

In Ethiopia, agriculture is the mainstay of the country and also the major resource of employment and income. About 85% of the population live in the rural area and are primarily engaged in agriculture and related activities. Thus, agriculture directly or indirectly forms an important component of the livelihood of more than 60 million people in the country Atesmachew et al. [1].

In Ethiopia, livestock contribute about 30-35% of agricultural gross domestic product (GDP) and more than 85% of the farm cash income Benin et al. [2]. Among African countries, Ethiopia is known by having the highest number of livestock population. According to the recent estimate of livestock population of the country, Ethiopia is a home for about 54 million cattle, 25.5 million sheep and 24.06 million goats. From the total cattle population 98.95% are local breeds and the remaining are hybrid and exotic breeds. 99.8% of the sheep and nearly all goat population of the country are local breeds CSA [3].

Sheep are the dominant livestock providing up to 63% of cash income and 23% of food substance value obtained from livestock production Bogale et al. [4] Ibrahim and Godefa [5]. Hence, an increase in sheep production enables to maintain self sufficiency in meat consumption for growing number of human population and also to increase export earnings Flecher and Zelalem [6]. However, this huge potential resources available in the country, several factors especially disease constraint their full utilization. The reason being predominance of infectious and parasitic disease, age old traditional management system, lack of genetic selection for good performance

coupled with under and malnutrition and absence of well-developed market infrastructure MoA [7]. From these the respiratory diseases have been identified as an important problem of sheep in the highlands of Ethiopia for the last two to three decades. It may account for up to 54% of the overall mortality of sheep in central high lands of Ethiopia Mukasa – Mugerwa et al. [8].

Among the respiratory diseases, Endo-parasites such as Dictyocaulidae and certain Metastrongylidae are known to exist in East Africa (Ethiopia, Kenya, and Tanzania) and South [9]. Lungworms particularly *Dictyocaulus filaria* can suppress the immunity of the respiratory tract [10] and causes death, poor weight gain or loss of body weight as well as greatly affects the potential productivity of sheep industry in the areas where it is prevalent.

Control of these parasites is essential for exploiting the potential of small ruminant production. For proper control, knowledge of parasitic diseases and their dynamics is essential. For this reason a study of epidemiology of each parasitic disease should be carried out in area where control is targeted Radostits et al. [11].

The incidence of parasitic diseases, including respiratory helminthiasis varies greatly from place to place depending on the relative importance of many factors. In this regard, although few studies were conducted so far in the North Shoa zone, there was no as such detail investigation to lungworm in Merhabete district. Thus, the present study was designed with the general objective of investigating the occurrence of ovine lungworm in the district. In line with this the specific objectives were to determine the prevalence of ovine lungworms and to assess the associated potential risk factors with the occurrence of lung worms.

Materials and Methods

Study area

The study was carried out from October to December, 2011 in Merhabete district of North Shoa Administrative Zone, Amhara National Regional State. The district is found in the central highlands of Ethiopia which is located at a distance of 180 km North of Addis Ababa.

The district covers 99540 hectares of land and divided in to 23 rural and 2 urban kebeles. The topographic data indicates that 20% plain, 15% mountain and 65% rugged. The altitude of the area varies from 1179-2644 m.a.s.l. The district has three agroclimatic zones with percent coverage of 5% highland, 65% midland and 30% lowland. The mean annual rainfall ranges between 838-1421 mm MARDO [12].

The total number of population of the district is 133448 out of this 88.86% dwell in the rural area and 11.14 dwell in urban area [12]. According to MARDO, basic data the population of livestock comprises of 121380 cattle, 9457 sheep, 40264 goats, 15289 equine and 64829 poultry.

Study animals

The study animals, sheep in the study area maintained under extensive system in small household flocks of mixed age groups and sexes and they were all indigenous (local breed) were included in the study.

Study design

Cross sectional type of study was carried out in Merhabete district starting from October to December 2011. Ten peasant associations were selected proportionally from each agro-climatic zone by using simple random sampling technique and a total of 384 animals were randomly selected from these areas. In this study, sex, age, respiratory signs, body condition and agro climate were considered as risk factors for the occurrence of lungworm in sheep and data related to these factors were recorded during faecal sampling. The age was categorized in to two groups (young and adult), those sheep with age less than two years were considered as young and greater or equal to two years adult Cringol et al. [13]. Regarding body condition, the animals categorized in to three groups (good, medium and poor body condition) and further grouped in to two based on clinical sign observed (i.e. coughing, nasal discharge, sneezing, dyspnea) [14].

Sample size determination and sampling technique

The sample size for this study was determined by using the formula given by Thrusfield [15], using simple random sampling technique was employed to select each and every animal included in the study. By rule of thumb where there is no information for an area it is possible to take 20% or 50% expected prevalence. Therefore, in this study the sample size is determined to be 384 by using 50% expected prevalence at 5% desired precision and 95 confidence interval as follows.

$$n = \frac{(Z^2 \times P(1-p))}{d^2} = \frac{1.962 \times 0.5(1-0.5)}{0.0025} = 384$$

Where, n= sample size

P= expected prevalence

D= desired level of precision (5%)

Study methodology

Faecal examination: Faecal samples were collected directly from the rectum of selected animals in screw capped glass bottle (universal bottle) and packed in ice box. While collecting faecal sample sex, age, body condition, respiratory sign and agro climate are properly recorded on the prepared format. In the laboratory, faecal sample examination for the presence of L1 larvae was conducted using modified Baermann technique Urquhart et al. [16]. Ten gram of faeces was taken and the specimens were wrapped enclosed with double layer of gauze fixed on to a string rod and submerged in a clean glass tube filled with warm water (approximately 40°C). The whole apparatus was left for 24 h overnight. So that the larvae left the faeces, migrated through the gauze and settled at the bottom of the glass finally the supernatant discarded Urquhart et al. [16]. After that, a small amount of (3-5 ml) fluids transfer in to a microscope slide using Pasteur pipette then it was examined under low power of the microscope. A drop of 1% iodine solution was added to the positive slides to immobilize the larvae for the identification of species Urquhart et al. [16]. Then, the result was recorded on the prepared format.

Data analysis

The data collected during sampling and laboratory findings were entered and stored in MS-excel. Stata 11 software package was used to perform the statistical analysis. Ovine prevalence was calculated by dividing the number of sheep infested with lungworm to the total number of sheep sampled. Pearson chi-square (χ^2) test was employed to assess the existence of association between occurrence of ovine lungworm and different potential risk factors considered in the study. For this analysis $P < 0.05$ were considered significant whereas $P > 0.05$ considered not significant.

Results

Prevalence of lungworm infection

Out of a total of 384 sheep examined over the study period, 52.34% (201/384) were positive for lungworm infection. The prevalence of *D. filaria*, *M. capillaris* and their mixed infection were found to be 136 (35.42%), 29 (7.55%) and 36 (9.4%), respectively (Table 1).

Lungworm species	No of sheep examined	No positive of	Prevalence (%)
<i>D. filaria</i>	384	136	35.42
<i>M. capillaris</i>	384	29	7.55
Mixed infection	384	36	9.37
Total	384	201	52.34

Table 1: Prevalence of ovine lungworm by parasitic species.

Risk factor analysis

In this study the following variables such as sex, age, respiratory signs, body condition and agroclimate zone were assumed to be risk factors for the occurrence of lungworm in sheep. The findings on these

factors and association between the prevalence of the disease and the risk factors were as presented here below.

Sex: The prevalence of ovine lungworm was higher in female (53.87%) than male (52.27%), however, no significant ($p>0.05$) difference was observed in prevalence rate of lungworms between sex (Table 2).

Sex	No of sheep examined	No of positive	Prevalence (%)
Female	245	132	53.87
Male	139	69	52.27
Total	384	201	52.34

Table 2: Prevalence of lungworm infection in male and female. $X^2=8.3546$, $P=0.138$.

Age: The age wise prevalence on this study showed that a little bit higher lungworm infection in young sheep (53.47%) than adult sheep (51.67%), however, the difference was not statistically significant ($p>0.05$) (Table 3).

Age	No of animals examined	No of positive	Prevalence (%)
Young	144	77	53.47
Adult	240	124	51.67
Total	384	201	52.34

Table 3: Prevalence of lungworm infection in different age groups. $X^2=9.8151$, $P=0.081$.

Respiratory signs: High prevalence of lungworm was observed in sheep that were showing clinical signs than apparently normal animals. The presence of clinical signs were significantly ($p<0.05$) associated with lungworm infection (Table 4).

Respiratory signs	No of animals examined	No positive of	Prevalence (%)
Absent	142	37	26.06
Present	242	164	67.77
Total	384	201	52.34

Table 4: Prevalence of lungworm infection in relation to respiratory signs. $X^2=72.9310$, $P=0.000$.

Body condition: In this study animals having poor body condition were found to have higher prevalence of ovine lungworm infection than moderate and good body conditions and the difference among the different body condition categories was statistically significant ($p<0.05$) (Table 5).

Body condition	No of animals examined	No of positive	Prevalence (%)
Poor	108	69	63.89
Moderate	268	130	48.51

Good	8	2	25
Total	384	201	52.34

Table 5: Prevalence of ovine lungworm infection based on body condition. $X^2=14.7887$, $P=0.014$.

Agro-climate: In the present study, the occurrence of lungworm was 54.17%, 57.95% and 41.88%, in highland, midland and low land areas, respectively. Statistically significant ($p<0.05$) variation in lungworm infection was observed among the three agro- climatic zones (Table 6).

Agro climates	No of animals examined	No of positive	Prevalence (%)
Highland	72	39	54.17
Midland	195	113	57.95
Lowland	117	49	41.88
Total	384	201	52.34

Table 6: Prevalence of ovine lungworm infection in relation to agro-climates. $X^2=54.2093$ $P=0.000$.

Discussions

The present study revealed the importance of lungworm infections. In these study area with an overall ovine lungworm infections rate were 52.34% these finding is closely agree with previous studies done by Tefera, [17] around kombolcha and Dessie, Sefinew [18] in six districts of Wollo and Habitu [19] in and around Debre Birhan with prevalence of 50%, 53.6% and 52.25% respectively. But it is relatively lower than reported by Zelalem [20], in Bassona Worena district with a prevalence of 62.67%. However it is higher than that of Regassa et al. [21] in and around Dessie and Kombolcha and Basaznew Bogale et al. [22] reported prevalence of 48.2% and 43.33% respectively. The variation in the overall prevalence rate in different areas might be due to differences in nutritional status, level of immunity, management practice of the animal, rain fall, humidity and temperature differences and season of examination on their respective study area Kebede et al. [23].

With regard to the species of lungworms, it was identified that *D. filaria* and *M. capillaries* occurred with prevalence of 35.42% and 7.55%, respectively. A mixed infection with the two lungworms was also occurred at prevalence of 9.37%. The prevalence of *D. filarial* in this finding is supported by [19] in and around [24], in Bassona Worena district with prevalence of 36.25% and 38.1% respectively. In contrast to these findings, sisay [25] in Bahir Dar and Basaznew Bogale et al. [22] in Dessie zuria district reported that *M. capillaries* were the most prevalent in their studies. The possible reason for the predominance of *D. filaria* might be attributed to the difference in the life cycles of the parasites. *D. filaria* has a direct life cycle and requires shorter time to develop to an infective stage. After ingestion, the larvae of these parasites can be shed with feces within 5 weeks. Unlike to *D. filaria*, the transmission of *M. capillaris* is epidemiologically complex event involving host, parasite and intermediate host [23,26].

In the current study higher level of prevalence were observed in female sheep than male but it was insignificant and this result agrees with that of [27], who reported insignificant difference of lungworm infections concerned on sheep sex. But contrast with the report of [25]

and [28] who reported significant difference of lungworm infection between male and female sheep. This high prevalence in female could be accredited to some of the physiological facts meaning the pre parturient relaxation of resistance can be result in the inability to expel the worm Craig, TM [29]. In addition farmers are kept male animals for different purposes like fattening, breeding and as a result male were given more dewormed than females.

This study showed that, the prevalence of lungworm infections affected by *D. filaria* and *M. capillaries* were observed higher prevalence in young sheep (53.47%) than adult sheep (51.66%), with no significant between the prevalence's of the different age groups. This report agree with Mekonnen et al. [30] who report that young sheep were found to be infected more than adults. This might be associated with apparent ability of the host to develop acquired immunity so that adult animals have the lowest infection and the lowest prevalence Urquhart et al. [16].

The prevalence of lungworm was significantly ($p < 0.05$) higher in the animal showing clinical sign (67.76%) than apparently normal (26.05%). This finding agrees with the result of [31] who reported the higher prevalence of lungworm infection in the animal showing clinical signs (86.8%) than apparently normal (57.1%). The reason attributed for such difference could be due to the stage of the parasite Fraser [32].

With regard to body condition, the prevalence of lungworm infection was higher (63.89%) in animals of poor body condition than those of medium (48.51%) and good (25%). The difference was significant ($p < 0.05$). This finding agreed with Muhammed et al. [33], Sisay [25] and Zelalem [20]. They reported that high prevalence was found in animals which had poor body condition. This might be associated with the nutritional management of animals. Poor body condition occurred as a result of lack of feed or nutritional management. This may lead to lack of resistance to infection and contribute for increased prevalence rate in poorly conditioned animals. Furthermore, considerable weight loss was associated with infection as a result of *D. filaria* [34], poorly nourished sheep and goat appeared to be less competent in getting rid of lungworm infection. Evidently, the infection with a parasite by itself might results in progressive emaciation of the animals [35]. The infestation by itself might results in progressive emaciation of the animals.

The prevalence of lungworm infection in various agro- climatic zone were shown significant difference ($p < 0.05$) in the study area. This is in line with the study result of Birtukan [28] in and around Debre Brhan. This might be due to the effect of altitude is attributable to climatic parameters. That is the survival and development of lungworm larvae is favoured by low moisture content and high humidity.

Conclusion and Recommendation

In general this study on ovine lungworm infection in Merhabete district revealed an overall prevalence of 52.34%. Two respiratory nematodes, *D. filaria* and *M. capillaries* were identified. It is found that animals under relatively good body condition, without respiratory signs and originated from lowland were less affected than those having poor body condition, with respiratory signs and originated from midland. *D. filaria* was found the most dominant lungworm species. Based on the above conclusion, the following points are recommended.

Animal health professionals should create awareness for animal owners to practice regular deworming of their animal.

The district administrative bodies should enforce application of rotational and/or zero grazing system.

Strategic anti-helmenthic drug treatment should be implemented.

Daily feed supplement according to the requirement should be exercised so as to improve body condition and immune resistance.

It is quite difficult to establish the seasonality of the infection on the basis of facts and figures presented by this study. Therefore, further works were recommended to study the seasonal pattern of lung worms and define other species in this region.
